**Abstract.** The increasing of forest fires highlights the importance of rapidly and accurately quantifying the burned areas, which is crucial evidence for determining the cause of fire and assigning responsibility. This study develops an operational tool based on the cloud-computing abilities of the PIE-Engine platform and Sentinel-2 satellite imagery. The burned areas are rapidly extracted by applying differential spectral indices such as dNDVI, dNBR and dNBR2 using the adaptive thresholds determined by the Otsu algorithm. Compared with field investigations, the accuracy of using a wildfire case in Liuhe Village, Hubei Province is high. The findings indicate that dNBR can achieve an area accuracy of 98.22 % and a pixel-level F1-score of 0.94, significantly higher than dNDVI. Although the accuracy of the random forest model is slightly high, the dNBR based method achieves an excellent balance between computational efficiency (about 2 s of processing time) and accuracy. In addition, we have developed a user-friendly web application that allows for custom parameter settings and visualizes results as a quantitative burned area map. This tool only requires a web browser, greatly reducing the technical barriers of remote sensing applications and providing a transparent, efficient, and accessible solution for supporting forest fire investigation and emergency response.

**Keywords:** wildfire investigation, burned area, spectral indices, cloud computing, PIE-Engine, Sentinel-2.

## 1. Introduction

Forest fires have significant impacts on ecosystems and socio-economic systems [1]. It will cause soil erosion, land cover changes [2], and significant greenhouse gas emissions [3], posing a threat to public safety and property [2]. In 2024, China recorded a total of 295 forest and grassland fires, including 292 forest fires and resulting in 13 fatalities. A survey showed that over 95 % of investigated forest fires were caused by human activities [4]. Intentionally or negligently signing forest fires constitutes a violation of the law. In serious cases, criminal responsibility will be pursued in accordance with the law [5]. Rapid estimation of burned area is crucial for post-fire investigations, and is the key basis for determining fire severity and assigning responsibilities [6, 7].

Traditional burned area assessment methods mainly rely on field surveys and manual digitization. Although they have high accuracy, these approaches are time-consuming, labor-intensive, and unsuitable for long-term repetitive monitoring [8]. Advances in remote sensing have greatly improved the ability to collect and analyze wildfire data through Earth observation, which is essential for fire investigations [9]. Although global burn area products based on remote sensing technology are available, there are still significant limitations [10]. For example, MODIS-derived low-resolution global burned area products such as MCD64A1 have significant omission errors in detecting small-scale fires under 100 hectares [11]. Therefore, to obtain accurate statistics on the fire coverage area, Landsat, Sentinel or higher-resolution images are required [12].

Many remote sensing methods have been proposed for burned area mapping, which are mainly categorized into two groups: bi-temporal spectral index differencing and machine learning classification [11, 13]. Although machine learning and deep learning methods, including architectures such as the hybrid BiLSTM-BiGRU models for efficient sequential data processing in network security [14], and object detectors such as YOLO variants [15-16], have shown high accuracy in complex pattern recognition. Their application to burned area mapping typically requires large amounts of high-quality training data, computationally intensive model development, and substantial hardware resources [17]. In addition, exporting trained classifiers in platforms requires complex programming and adaptation [18]. In contrast, the spectral index methods have high computational efficiency, is easy to implement, and is easy to transfer across platforms, making them particularly effective in rapidly delineating fire perimeters [19-20]. However, the application of the threshold-based spectral index methods is limited due to their sensitivity to vegetation type, phenology, and atmospheric conditions [21-23]. Dynamic thresholding algorithms and machine learning classifiers such as Random Forest have been proposed to improve robustness [24-25]. However, integrating them into user-friendly tools that can be operated by field investigators remains challenging. Recent cross-domain studies have further demonstrated the versatility of adaptive thresholding and lightweight models in resource-constrained environments [26-28].

The exponential growth of remote sensing data volumes over decades has brought technical challenges to data transmission, storage, and processing, due to the complex spectral and spatial characteristics of these images [29-30]. Utilizing the potential of remote sensing requires advanced technical skills and, in most cases, proficient programming [31]. Therefore, fire investigators may be unwilling or inadequately to effectively utilize remote sensing datasets [32]. Cloud-based remote sensing platforms (represented by Google Earth Engine (GEE)) equipped with supercomputing capabilities have proven effective for storing, processing, and analyzing massive amounts of remote sensing data [33]. At the same time, cloud platforms in China are developing rapidly. It is worth noting that PIE-Engine, developed by PIESAT Information Technology Co., Ltd., has achieved significant progress [34]. Locally developed platforms such as PIE-Engine provide Chinese-language interfaces, reducing implementation barriers and better meeting the practical needs of grassroots fire investigations [35]. In addition, these platforms may be integrated into smart city frameworks for environmental monitoring and emergency response, in line with the emerging trends of ethical and governance-aware urban sensing systems [36].

Combined multi-temporal Sentinel-2 imagery with adaptive thresholding techniques, a customizable tool based on the PIE-Engine cloud platform is developed for rapid extraction of burned areas. Main contributions are manifested in the following three aspects:

- (1) A lightweight extraction framework that combines multiple spectral indices (dNDVI, dNBR, dNBR2) with the Otsu adaptive thresholding method is proposed. This framework can significantly reduce computational and operational barriers while maintaining high accuracy.
- (2) An interactive application on the PIE-Engine platform that supports user-defined parameters (such as the study area, time range, and spectral indices) is constructed. This implements a “ready-to-adjust-and-use” feature, facilitating on-site investigation.
- (3) The accuracy and efficiency of this tool are validated through a typical wildfire case study. Comparing the results with those from traditional thresholding methods and field surveys, the applicable scope and limitations of this tool are verified.

## 2. Material and research method

### 2.1. Study area and data sources

Liuhe Village lies in the eastern mountainous region of Xugu Town, Xinzhou District, Wuhan (115°02'01"E-115°02'37"E, 30°53'55"N-30°54'13"N). The study area covers an area of 1,200 hectares, including 70.87 hectares of farmland and 516.2 hectares of forested land. This

region is characterized by a subtropical monsoon climate with abundant rainfall and high temperatures during the synchronous rainy and hot seasons. The terrain is dominated by low hills and mountains, and the vegetation is mainly composed of highly flammable pine trees and understory grasses. On October 4, 2019, extreme drought and elevated temperatures triggered a forest fire near Liuhe Village, and the fire danger index continued to reach its maximum level (red alert). Field surveys conducted on December 21, 2019 used a GPS data collector (Unistrong MG758) to record the boundaries of burn scars. The integration with satellite imagery during post-processing confirmed that the burned area was 106.25 hectares (Fig. 1).

This study used Sentinel-2 satellite data accessed by the PIE-Engine platform (<https://engine.piesat.cn/engine/home>). The Sentinel-2 mission, operated by the European Space Agency, used twin satellites (Sentinel-2A and 2B) to achieve a combined 5-day revisit cycle. Each satellite was equipped with a Multispectral Imager (MSI) that can capture 13 spectral bands in the visible, near-infrared (NIR), and shortwave infrared (SWIR) regions, with a spatial resolution of up to 10 m. We used the Level-2A Bottom-of-Atmosphere reflectance products (Dataset ID: "S2/L2A") provided by PIE-Engine.

**Fig. 1.** Location of the study area. Source: National Geomatics Center of China, Tianditu imagery base map [GS(2025)1508], retrieved March 2025, from <https://www.tianditu.gov.cn>

## 2.2. Advantages of data preprocessing and platform computation

One of the core advantages of implementing this method on the PIE-Engine platform is the use of its cloud-native parallel computing architecture. Unlike traditional desktop remote sensing software (such as ENVI and ArcGIS) that requires downloading, local storage, and sequential processing of large satellite image datasets (a process often taking minutes to hours), PIE-Engine performs these computations in parallel on its servers. This architecture allows for near-instantaneous access, preprocessing, and analysis of Sentinel-2 imagery directly in the web browser, which is crucial for achieving the fast-processing times. A web-based application was designed to visualize results, featuring automated threshold calculation, manual threshold adjustment, and binary map generation. The workflow is shown in Fig. 2.

Sentinel-2 Level-2A images are provided by PIE-Engine with atmospheric correction. For each image including the study region and period, the cloudMask function is used for cloud removal. False-color synthesis was generated by assigning SWIR (Band 12), NIR (Band 8), and red (Band 4) bands to the RGB channels respectively to improve the visibility of burned scars. All available cloud-free images were fused and clipped to the study area boundary, and resampled to

are solution of 10 m. Fig. 3 shows the pre-fire and post-fire false-color synthesis.

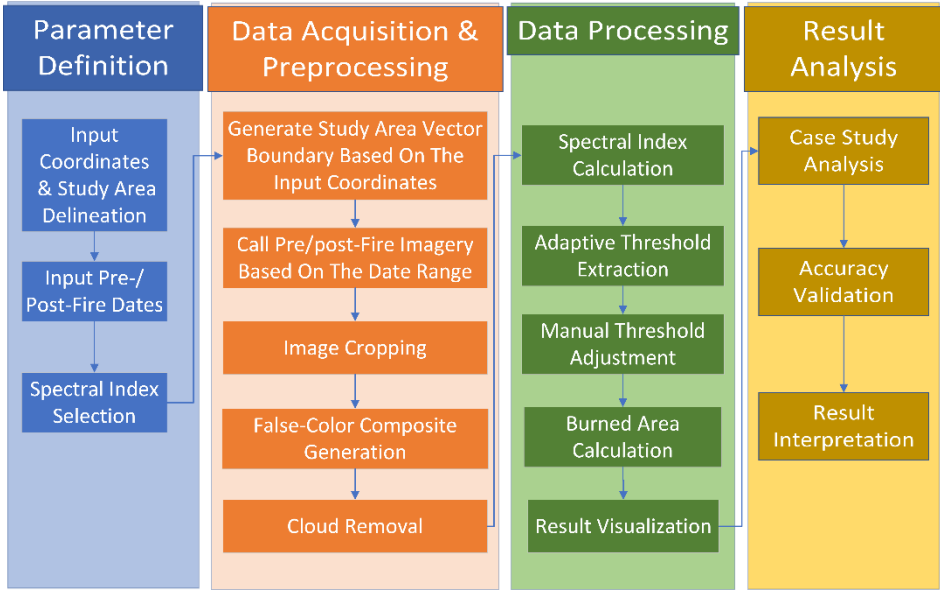

Fig. 2. Flowchart of the methodology

Fig. 3. Sentinel-2 false color composite images a) before and b) after the fire

### 2.3. Spectral index calculation

For the pre- and post-fire image synthesis, three spectral indices are calculated as follows:

1) Normalized Difference Vegetation Index (NDVI) [37]:

$$NDVI = \frac{\rho_{B8} - \rho_{B4}}{\rho_{B8} + \rho_{B4}} \quad (1)$$

2) Normalized Burn Ratio (NBR) [38]:

$$NBR = \frac{\rho_{B8} - \rho_{B12}}{\rho_{B8} + \rho_{B12}} \quad (2)$$

3) Normalized Burn Ratio 2 (NBR2) [39]:

$$NBR2 = \frac{\rho_{B8} - \rho_{B11}}{\rho_{B8} + \rho_{B11}} \quad (3)$$

where  $\rho_{B4}$ ,  $\rho_{B8}$ ,  $\rho_{B11}$ , and  $\rho_{B12}$  represent the BOA reflectance values of Sentinel-2 Band 4 (Red, 665 nm), Band 8 (NIR, 842 nm), Band 11 (SWIR1, 1610 nm), and Band 12 (SWIR2, 2190 nm), respectively.

The difference indices (dNDVI, dNBR, dNBR2) were calculated by subtracting the pre-fire index value from the post-fire index value for each pixel [40], with an output resolution of 10 m.

## 2.4. Threshold extraction and area calculation

The Otsu algorithm is used to obtain an adaptive threshold for segmenting burned areas from each difference index image [41]. The algorithm finds the threshold  $T$  that maximizes the inter-class variance between the foreground (burned) and background (unburned) pixel classes:

$$T = w_0 * (u_0 - u)^2 + w_1 * (u_1 - u)^2, \quad (4)$$

where  $w_0$  and  $w_1$  are the probabilities of the two classes separated by threshold  $T$ ;  $u_0$  and  $u_1$  are the mean intensities of the two classes, and  $u$  is the global mean intensity of the difference image.

Although the Otsu threshold ( $T_{Otsu}$ ) provides a statistically robust starting point, errors in residual commission (unburned areas classified as burned) or omission (missed burned areas) may occur in heterogeneous landscapes. To address this, this tool includes a manual adjustment interface. Users can fine-tune the final threshold ( $T_{final}$ ) by applying a constant offset ( $\Delta$ ) to  $T_{Otsu}$ :  $T_{final} = T_{Otsu} + \Delta$ , where  $\Delta$  can be increased or decreased in steps of 0.05 based on visual inspection of the preliminary binary map and local knowledge. This simple and effective post-Otsu adjustment allows users to account for spectral changes at specific locations. The core adaptive thresholding framework (Otsu + manual calibration) is universal and can be reused to detect other anomalies (such as floods, and deforestation) by replacing the input spectral indices with relevant ones (such as NDWI for water).

The burned area ( $A$ ) in hectares is calculated as:  $A = N_{burnedpixels} * \frac{10*10}{10000} = N_{burnedpixels} * 0.01$ , where  $N_{burnedpixels}$  is account of pixels classified as burning.

## 2.5. Web-based user interface

The entire workflow runs locally in the PIE-Engine platform. A browser-accessible interface is built with the UI components of the platform: the InputNumber widgets for coordinate and threshold offset ( $\Delta$ ), the DateSelect components for defining pre-fire and post-fire time ranges, the Select dropdowns for selecting the spectral index, and a Button for trigger processing. All widgets are nested in a Panel container for a responsive layout. After execution, the application will display an interactive map with a binary burned area mask and output the calculated area in hectares.

## 2.6. Accuracy assessment

The main accuracy of the burned area range is evaluated by comparing the remotely sensed estimates ( $S_i$ ) with the ground-surveyed reference area ( $S_{ref} = 106.25$  ha). The area accuracy  $P_{area}$  (%) was calculated as follows:

$$P_{area} = \left( 1 - \left| \frac{S_i - S_{ref}}{S_{ref}} \right| \right) \times 100\%. \quad (5)$$

To enhance the quantitative evaluation, we have added pixel-level classification metrics from a stratified random sample of points ( $n = 500$ ). This sample is used to calculate the confusion matrix and obtain the following standard classification indicators:

Accuracy (User Accuracy): Measures the reliability of the classification, that is, the proportion

of predicted burned pixels that are actually burned:

$$P = \frac{TP}{TP + FP}. \quad (6)$$

Recall (Producer Accuracy): Measures the completeness of the classification, that is, the proportion of actual burned pixels that are correctly identified:

$$R = \frac{TP}{TP + FN}. \quad (7)$$

F1-Score: the harmonic mean of accuracy and recall, providing a single balanced metric:

$$F1 = 2 * \frac{P * R}{P + R}. \quad (8)$$

Cohen's Kappa Coefficient ( $\kappa$ ): Measures the consistency between classification and reference data, exceeding accidental expectations:

$$\kappa = \frac{P_0 - P_e}{1 - P_e}, \quad (9)$$

where  $TP$  (True Positives) is the number of pixels correctly classified as burned;  $FP$  (False Positives) refers to the number of pixels incorrectly classified as burned (commission error), and  $FN$  (False Negatives) is the number of burned pixels incorrectly classified as unburned (omission error).  $P_0$  is the observed agreement (overall accuracy), and  $P_e$  is the expected accidental consistency calculated based on the marginal sum of the confusion matrix.

In addition, a comparative experiment was conducted to place the performance of this index-based method in the background. A Random Forest (RF) classifier is implemented on the same PIE-Engine platform using the pre-fire and post-fire reflectance values of bands B2, B3, B4, B8, B11, and B12 as features. The model is trained on a separate set of labeled data from the same event. Its performance (Precision, Recall, F1, Kappa) and computational execution time are compared with the dNBR+Otsu method to highlight the trade-offs between accuracy, complexity, and operational efficiency.

### 3. Results and analysis

#### 3.1. User interface and processing efficiency

The web application developed on the PIE-Engine platform demonstrated efficient burned area extraction through its intuitive interface and robust processing algorithms. As shown in Fig. 4, there is a parameter configuration panel (Fig. 4(a)) on the left sidebar of the interface. It is used to define the area coordinates, temporal ranges, and processing thresholds. The system automatically selects optimal pre-fire and post-fire Sentinel-2 scenes in the user-specified date range. The calculation results include the adaptive thresholds and area metrics, which are dynamically shown in the lower left panel (Fig. 4(b)). The central mapping area (Fig. 4(c)) visualizes the results, and the layer management module (Fig. 4(d)) allows for flexible switching of layers. This responsive design ensures full functionality in devices without the need to specialized software.

#### 3.2. Automatic burned area identification

Fig. 5 shows the adaptive-threshold burned area maps generated within about 2 s. There are significant performance differences between the indicators. The dNBR index produces the most

spatially coherent results with minimal noise (Fig. 5(b)). The dNDVI output contains a significant amount of noise and omission errors, particularly misclassifying terrain shadows in northwestern regions due to its known sensitivity to illumination variations, atmospheric interference, and solar geometry effects (Fig. 5(a)). The dNBR2 index performs moderately and effectively distinguishes agricultural changes in eastern farmlands (Fig. 5(c)). Common challenges include false alarms caused by human interference near settlements, seasonal errors in agricultural classification, and incorrect delineation of water-vegetation boundaries during hydrological fluctuations. These limitations highlight the complex interactions between spectral signatures and landscape changes in post-fire environments.

Fig. 4. User interface and main functions of the application

Fig. 5. Burned area maps recognized by adaptive threshold of: a) dNDVI; b) dNBR; c) dNBR2

### 3.3. Quantitative accuracy and comparative evaluation

Quantitative assessment confirms the superiority of dNBR. The adaptive thresholding approach using dNBR achieve an area accuracy ( $P_{area}$ ) of 98.22 % (108.14 ha compared to the ground truth of 106.25 ha) at an optimal threshold of 0.32 (Table 1). The pixel-level classification metrics obtained from 500 validation points provide a more detailed evaluation (Table 1). dNBR achieves the highest F1-score (0.94) and Kappa coefficient (0.92), indicating an excellent balance between precision (0.95) and recall (0.93). Although manually adjusted dNDVI can achieve a high area accuracy (99.64 %), this comes at the cost of a severe damage recall (0.71), leading to significant omission errors and a lower F1-score (0.81). The visual examination of the results (Figs. 6-7) confirms that the dNBR adaptive thresholding approach best balances the accuracy and reliability, effectively minimizing omission and commission errors while maintaining the integrity of burn scar.

**Table 1.** Accuracy assessment of burned area extraction using different spectral indices

Spectral indexes	Area (ha)	$P_{area}$ (%)	Precision	Recall	F1-Score	Kappa ( $\kappa$ )
dNDVI	108.92	84.48	0.87	0.76	0.81	0.78
dNBR	108.14	98.22	0.95	0.93	0.94	0.92
dNBR2	113.36	93.31	0.91	0.94	0.92	0.89
Random forest	105.89	99.66	0.97	0.96	0.96	0.95

To address the uncertainty of boundary delineation, a 30-meter buffer zone around the reference fire perimeter is analyzed. In this boundary region, the dNBR method maintains a high classification accuracy (Producer accuracy > 90 %), indicating robust performance in distinguishing the gradient between burned and live vegetation, although some inevitable edge pixel mixing. A Random Forest (RF) classifier is implemented on the PIE-Engine for comparison. As shown in Table 1, the RF model achieves a slightly higher pixel-level accuracy (F1 = 0.96,  $\kappa$  = 0.95) and area accuracy (99.66 %). However, its execution time on the cloud platform is significantly longer (about 45 s for model prediction) than the near-instantaneous processing (about 2 s) of the dNBR+Otsu method. This comparison highlights the trade-off empirically: although advanced machine learning can provides light accuracy gains, this spectral index method achieves an excellent balance between computational efficiency, operational simplicity, and “good-enough” accuracy for rapid responses.

**Fig. 6.** Accuracy evaluation result of burned area after threshold adjustment

### 3.4. Ethical, social, and practical implications

The deployment of automated remote sensing tools for forest fire analysis is of great importance. First, regarding transparency and algorithmic decision-making, the proposed methodology (Otsu on dNBR) is fully transparent and deterministic. This contrasts with “black-box” deep learning models and is crucial for generating evidence that can be carefully examined and interpreted in policy-making or legal liability assessments. Then environmental and privacy

considerations must be balanced. Although satellite monitoring is indispensable for environmental protection and disaster management, its use must be balanced with privacy regulations, especially when capturing private property with high-resolution data. This tool uses medium-resolution Sentinel-2 data (10 m), which can alleviate personal privacy while still being suitable for area-based damage assessment. Finally, ensuring fair access to such technology is a key practical issue. The design of this tool on the cloud-based PIE-Engine platform directly addresses this only using a web browser, thereby eliminating the need for expensive computing hardware or specialized software licenses. This is particularly beneficial for forestry departments or researchers in regions with limited technical infrastructure, reducing the barrier to advanced geospatial analysis.

Fig. 7. Burned area map recognized by adjusted threshold (0.21) for dNDVI

#### 4. Conclusions

This study developed and validated an operational tool on the PIE-Engine cloud platform for rapid burned area extraction using Sentinel-2 imagery. The objectives of creating a user-friendly tool using cloud computing to evaluate the performance of key spectral indices and demonstrate a practical solution for fire investigation are achieved. The key findings are as follows:

1) The PIE-Engine-based tool can effectively generate burned area maps and calculate affected areas using medium-resolution Sentinel-2 data. Its cloud-native architecture and parallel computing resources enable processing times to be about 2 s, overcoming the efficiency limitations of traditional desktop software workflows. The developed tool provides a scientifically reliable and browser-accessible alternative to field-intensive surveys, significantly improving operational applicability.

2) Comparative analysis show that there are substantial performance differences in the three spectral indices. Although dNDVI has higher accuracy after manual threshold adjustment (increasing from 84.48 % to 99.64 %), it consistently produces erroneous pixels and is not recommended as the primary burned area extraction index. In contrast, the combination of dNBR with Otsu adaptive thresholding shows optimal performance in burn scar identification and area calculation. The adaptive thresholding results (an area accuracy of 98.22 %, F1-score of 0.94) confirms the findings of Sukmono et al. [42]. Its ability to provide high accuracy without manual intervention makes dNBR the preferred choice for operational applications.

3) The tool provides a cost-effective and reliable solution for rapid assessment. Although the accuracy of the Random Forest model is slightly high, its longer processing time highlights the advantages of the proposed method: providing sufficiently accurate results with maximal speed and minimal complexity, which is often the priority in initial post-fire emergency response and investigation.

Future work will focus on three enhancements: (a) Assessing and improving the algorithm's universality and transferability through testing in different ecological zones; (b) Reducing errors from agricultural areas and shadows using non-forest masking and additional filtering criteria; and

(c) Increasing flexibility by integrating multi-source satellite data to improve temporal resolution. The transferability and broader “global applicability” of the framework will be validated through extensive multi-regional case studies in subsequent research.

**Lijun Mao** received her Ph.D. degree in forest management from Nanjing Forestry University, Nanjing, China, in 2022. She now works at the University. Her current research interests include forestry remote sensing and forest fire prevention.

**Tianxiang Zhou** received his Bachelor of Engineering degree from Nanjing Police College, Nanjing, China, in 2024. He now works at a government agency. His current research interests include practical police operations.

**Chenghui Nan** received his Ph.D. degree in botany from Nanjing Forestry University, Nanjing, China, in 2012. He now works at the university. His current research interests include forest resource inventory.
